

The 60-month all-sky BAT Survey of AGN and the Anisotropy of Nearby AGN

M. Ajello¹, D. M. Alexander², J. Greiner³, G. M. Madejski¹, N. Gehrels⁴ and D. Burlon³

ABSTRACT

Surveys above 10 keV represent one of the the best resources to provide an unbiased census of the population of Active Galactic Nuclei (AGN). We present the results of 60 months of observation of the hard X-ray sky with *Swift*/BAT. In this timeframe, BAT detected (in the 15–55 keV band) 720 sources in an all-sky survey of which 428 are associated with AGN, most of which are nearby. Our sample has negligible incompleteness and statistics a factor of ~ 2 larger over similarly complete sets of AGN. Our sample contains (at least) 15 bona-fide Compton-thick AGN and 3 likely candidates. Compton-thick AGN represent a $\sim 5\%$ of AGN samples detected above 15 keV. We use the BAT dataset to refine the determination of the LogN–LogS of AGN which is extremely important, now that NuSTAR prepares for launch, towards assessing the AGN contribution to the cosmic X-ray background. We show that the LogN–LogS of AGN selected above 10 keV is now established to a $\sim 10\%$ precision. We derive the luminosity function of Compton-thick AGN and measure a space density of $7.9^{+4.1}_{-2.9} \times 10^{-5} \text{ Mpc}^{-3}$ for objects with a de-absorbed luminosity larger than $2 \times 10^{42} \text{ erg s}^{-1}$. As the BAT AGN are all mostly local, they allow us to investigate the spatial distribution of AGN in the nearby Universe regardless of absorption. We find concentrations of AGN that coincide spatially with the largest congregations of matter in the local ($\leq 85 \text{ Mpc}$) Universe. There is some evidence that the fraction of Seyfert 2 objects is larger than average in the direction of these dense regions.

1. Introduction

There is a general consensus that the cosmic X-ray background (CXB), discovered more than 40 years ago (Giacconi et al. 1962), is produced by integrated emission of Active Galactic Nuclei (AGN). Indeed, below ~ 3 keV sensitive observations with Chandra and XMM-Newton have directly resolved as much as 80 % of the CXB into AGN (Worsley et al. 2005; Luo et al. 2011). However, above 5 keV, due to the lack of sensitive observations, most of the CXB emission is at present unresolved. Population synthesis models have successfully shown, in the context of the AGN unified theory (Antonucci 1993), that AGN with various level of obscuration and at different redshifts can account for 80–100% of the CXB up to ~ 100 keV (Comastri et al. 1995; Gilli et al. 2001; Treister & Urry 2005). In order to reproduce the spectral shape and the intensity of the CXB, these models require that Compton-thick AGN ($N_H \geq 1.4 \times 10^{24} \text{ cm}^{-2}$) contribute ~ 10 % of the total CXB intensity. With such heavy absorption Compton-thick AGN have necessarily to be numerous, comprising perhaps up to 30–50 % of the AGN population in the local Universe (e.g. Risaliti et al. 1999). However, it is still surprising that only a very small fraction of the population of Compton-thick AGN has been uncovered so far (Comastri 2004; Della Ceca et al. 2008a, and references therein).

Studies of AGN are best done above 10 keV where the nuclear radiation pierces through the torus for all but the largest column densities. Focusing optics like those mounted on NuSTAR and ASTRO-H (respectively, Harrison et al. 2010; Takahashi et al. 2010) will allow us to reach, for the first time, sensitivities $\leq 10^{-13} \text{ erg cm}^{-2} \text{ s}^{-1}$ above 10 keV permitting us to resolve a substantial fraction of the CXB emission in this band. Given their small field of views (FOVs) those instruments will need large exposures in order to gather reasonably large AGN samples. Because of their good sensitivity the AGN detected by NuSTAR and ASTRO-H should be at redshift ~ 1 , but, due to the small area surveyed, very few if any will be at much lower redshift.

All-sky surveys, like those performed by *Swift*/BAT and INTEGRAL above 10 keV are very effective in making a census of nearby AGN, thus providing a natural extension to more sensitive (but with a narrower FOV) missions. Here we report on the all-sky sample of AGN detected by BAT in 60 months of exposure. Our sample comprises 428 AGN detected in the whole sky and represents a factor of ~ 2 improvement in number statistics when compared to previous complete samples (e.g. Burlon et al. 2011). In this paper, we present the sample and refine the determination of the source count distribution and of the luminosity function of AGN. This is especially important considering the upcoming launch of NuSTAR (scheduled for March 2012) as it allows us to make accurate predictions for the expected space densities of distant AGN. We also use the BAT sample to investigate the spatial distribution of AGN in the local Universe. We leave for an upcoming publication the follow-up of all new sources

using 2–10 keV data and the determination of the absorption distribution.

This paper is organized as follows: the BAT observations are discussed in § 2, while § 3.1 and § 3.2 discuss respectively the source count distribution and the luminosity function of AGN. In § 4 we present a measurement of the over-density of AGN in the local Universe, while in § 5 the prospects for the detection of AGN by NuSTAR are discussed in the framework of the BAT observations and population synthesis models. Finally, § 6 summarizes our findings. Throughout this paper, we assume a standard concordance cosmology ($H_0=71 \text{ km s}^{-1} \text{ Mpc}^{-1}$, $\Omega_M=1-\Omega_\Lambda=0.27$).

2. Properties of the Sample

The Burst Alert Telescope (BAT; Barthelmy et al. 2005) onboard the *Swift* satellite (Gehrels et al. 2004), represents a major improvement in sensitivity for imaging of the hard X-ray sky. BAT is a coded mask telescope with a wide field of view (FOV, $120^\circ \times 90^\circ$ partially coded) aperture sensitive in the 15–200 keV range. Thanks to its wide FOV and its pointing strategy, BAT monitors continuously up to 80% of the sky every day achieving, after several years, deep exposures across the entire sky. Results of the BAT survey (Markwardt et al. 2005; Ajello et al. 2008a; Tueller et al. 2008) show that BAT reaches a sensitivity of $\sim 1 \text{ mCrab}^1$ in 1 Ms of exposure. Given its sensitivity and the large exposure already accumulated in the whole sky, BAT is an excellent instrument for studying populations whose emission is faint in hard X-rays.

For the analysis presented here we use 60 months of *Swift*/BAT observations taken between March 2005 and March 2010. Data screening and processing was performed according to the recipes presented in Ajello et al. (2008a) and Ajello et al. (2008b). The chosen energy interval is 15–55 keV. The all-sky image is obtained as the weighted average of all the shorter observations. The final image shows a Gaussian normal noise and we identified source candidates as those excesses with a signal-to-noise (S/N) ratio $\geq 5\sigma$. The final sample comprises 720 sources detected all-sky. Identification of these objects was performed by cross-correlating our catalog with the catalogs of Tueller et al. (2008), Cusumano et al. (2010), Voss & Ajello (2010), and Burlon et al. (2011). Whenever available we used the newest optical identifications provided by Masetti et al. (2008), Masetti et al. (2009), and Masetti et al. (2010). Of the 720 all-sky sources only 37 (i.e. $\sim 5\%$) do not have a firm identification. This small incompleteness does not change when excluding or including the Galactic plane. Of the 720 objects, 428 are identified with AGN. This represents an improvement

¹1 mCrab in the 15–55 keV band corresponds to $1.27 \times 10^{-11} \text{ erg cm}^{-2} \text{ s}^{-1}$

of a factor >2 in the number of detected AGN with respect to previous complete samples (e.g. Ajello et al. 2009b; Burlon et al. 2011). Cusumano et al. (2010) recently reported on the sample of sources detected by BAT in 58 months of observations. Their catalog is constructed using three energy bands and selecting $\geq 4.8\sigma$ excesses in any of the three bands. As such their catalog is larger than the one presented here. However, for the scope of this and future analyses (e.g. a follow-up work of that presented in Burlon et al. 2011) it is important to have a clean sample whose selection effects are well understood and can be accounted for during the analysis.

Fig. 1 shows the sky coverage of the BAT survey. It is apparent that the limiting flux is ~ 0.45 mCrab ($\sim 5.5 \times 10^{-12}$ erg cm $^{-2}$ s $^{-1}$) and that the BAT survey becomes complete (for the whole sky) for source fluxes ≥ 1 mCrab. The sensitivity scales nicely with the inverse of the square root of the exposure time as testified by the limiting sensitivity of 0.6 mCrab reached in 36 months of observations (Ajello et al. 2009a).

Fig. 1.— Sky coverage of the BAT survey for the 15–55 keV band and for sources detected all-sky above the 5σ level.

2.1. Jet-dominated and Disk-dominated Objects

Jet-dominated AGN (radio galaxies and blazars) constitute a $\sim 15\%$ fraction of the BAT samples (e.g. see Ajello et al. 2009b). This is confirmed also here where 67 (out of

^aThe full table is available in the online version of the paper.

^bAGN are sources lacking an exact optical classification.

Fig. 2.— Position on the luminosity-redshift plane of the 428 AGN detected by BAT in the 15–55 keV band. The color coding reflects the optical classification reported in Tab. 1. AGN are sources lacking an exact optical classification. The black squares mark the position of the Compton-thick AGN reported in Tab. 2. Note that their luminosities were not corrected for absorption (see text for details). The dashed line shows the flux limit of the BAT survey of $5.5 \times 10^{-12} \text{ erg cm}^{-2} \text{ s}^{-1}$.

the 428 AGN) are classified as either radio-galaxies or blazars. The remaining 361 AGN are associated with objects optically classified as Seyfert galaxies (323 objects) or with nearby galaxies (38 sources), through the detection of a soft X-ray counterpart, for which an optical classification is not yet available. The full sample is reported in Tab. 1. For all the sources, k -corrected L_X luminosities were computed according to:

$$L_X = 4\pi d_L^2 \frac{F_X}{(1+z)^{2-\Gamma_X}} \quad (1)$$

where F_X is the X-ray energy flux in the 15–55 keV band and Γ_X is the photon index. This assumes that the source spectra are adequately well described by a power law in the 15–

55 keV band in agreement with what found by Ajello et al. (2008b), Tueller et al. (2008), and Burlon et al. (2011). Unless noted otherwise (i.e. § 3.3) luminosities are not corrected for absorption along the line of sight since this correction is different than unity (in the 15–55 keV band) only for Compton-thick AGN (see Fig. 11 in Burlon et al. 2011) and does not introduce any apparent bias in any of the results shown in the next sections.

Fig. 2 shows the position of the 428 sources in the luminosity-redshift plane for the different optical classifications reported in Tab. 1. The BAT AGN sample spans almost 8 decades in luminosity and includes sources detected from $z \approx 0.001$ (i.e. ~ 4 Mpc) up to $z \approx 4$. It is also evident that Seyfert galaxies dominate the low-luminosity part of the sample, while blazars and radio-galaxies dominate the high-luminosity part of the sample. The increased exposure of BAT allows us to detect fainter AGN with respect to previous samples. Indeed, the average flux of the Seyfert-like AGN decreased by $\sim 20\%$ when comparing it to the sample of AGN reported in Burlon et al. (2011). Since the average redshift in the two samples is very similar, this translates into a larger number of low-luminosity AGN.

2.2. Compton-thick AGN

Hard X-ray selected samples are among the best resources to uncover Compton-thick AGN which are otherwise difficult to detect. A detailed measurement of the absorbing column density of all the AGN in this sample is beyond the scope of this paper and left for a future publication. However, in order to determine the likely candidates, it is possible to cross-correlate our source list with catalogs of Compton-thick AGN. Our AGN catalog contains all the 9 Compton-thick AGN reported by Burlon et al. (2011) and 6 additional Compton-thick AGN reported in the list of bona-fide objects of Della Ceca et al. (2008a). There 3 additional sources which are labeled as Compton-thick candidates by Della Ceca et al. (2008a) (see their Table 2) which are also detected in this sample. The full list of 18 known Compton-thick AGN contained in this sample is reported in Tab. 2. It is clear that the number of (likely) Compton-thick AGN is doubled with respect to the sample of Burlon et al. (2011) and that Compton-thick AGN represent a ‘steady’ 5% fraction (i.e. $\sim 18/361$) of AGN samples selected above 10 keV.

The redshift distribution of Compton-thick AGN is also different than that of the whole AGN sample. The median redshift of the Compton-thick AGN of Tab. 2 is 0.010 while that one of the entire AGN sample is 0.029. Compton-thick AGN can be detected by BAT only within a distance of ~ 100 Mpc beyond which the strong flux suppression caused by the Compton-thick medium limits the capability of BAT to detect these objects.

We also checked if any of the remaining 3 bona-fide Compton-thick AGN (or the 20 remaining candidates) reported in Della Ceca et al. (2008a) lie just below the reliable BAT detection threshold. None of the remaining sources in the above lists exhibits a significance larger than 3.5σ in our analysis. This means that none of these sources are likely to be detectable by BAT in a deeper survey. The main consequence is however that the new Compton-thick objects that will appear in the BAT samples will be new (i.e. previously un-studied) sources. A few might already be present in this sample and this aspect will be investigated in a follow-up study.

Table 2. Known Compton-thick AGN detected in the BAT sample. Unless written explicitly the values of the absorbing column density come from Burlon et al. (2011).

^aPart of the sample of candidate Compton-thick objects in Della Ceca et al. (2008a).

^bNGC 1365 is a complex source that shows a column density that can vary from $\text{Log}N_H \approx 23$ to ≥ 24 on timescales of ~ 10 hr (Risaliti et al. 2009b). According to Risaliti et al. (2009a) the source has an absorber with $\text{Log}N_H \approx 24.6$ which covers $\sim 80\%$ of the source.

^cUGC 4203 (also called the ‘Phoenix’ galaxy) is known to exhibit changes in the absorbing column density from the Compton-thin to the Compton-thick regime (see e.g. Risaliti et al. 2010).

^dReported to be Compton-thick by Reynolds et al. (1994), and Bassani et al. (1999).

^eFor the value of the absorbing column density see Della Ceca et al. (2008a) and references therein.

^fPiconcelli et al. (2011) reports that this source might be absorbed by $\text{Log}N_{\text{H}} \geq 25$.

3. Statistical Properties

3.1. The Source Count Distribution

The source count distribution of radio-quiet AGN (also called LogN–LogS) has already been derived above 10 keV by several authors (e.g. Ajello et al. 2008b; Tueller et al. 2008; Ajello et al. 2009b; Krivonos et al. 2010). Here we use our larger complete set of AGN to refine the determination of the LogN–LogS which is of particular interest since NuSTAR will be surveying, with a factor >100 better sensitivity, a similar energy band in the very near future. Our aim is also to compare the BAT observations to the predictions of popular population synthesis models.

In order to account robustly for uncertainties in the determination of the LogN–LogS we perform a bootstrap analysis, creating 1000 resampled set extracted (with replacement) from the BAT dataset. We perform a maximum likelihood fit (see Ajello et al. 2009b, for details) to each data set with a power law of the form:

$$\frac{dN}{dS} = A * (S/10^{-11})^{-\alpha} \quad (2)$$

where S is the source flux, and α and A are respectively the slope and the normalization of the power law. From the 1000 realizations of the BAT AGN set we derive the distributions of the normalization and of the slope and we use these to determine the best-fit parameters and their associated errors.

From our analysis we find the best-fit values of: $\alpha=2.49^{+0.08}_{-0.07}$ and $A=1.05^{+0.04}_{-0.04} \times 10^9$. So the BAT LogN–LogS is compatible with Euclidean for all fluxes spanned by this analysis as shown in Fig. 3. The surface density of AGN at fluxes (15–55 keV) greater than 10^{-11} erg cm $^{-2}$ s $^{-1}$ is $6.67^{+0.11}_{-0.12} \times 10^{-3}$ deg $^{-2}$ which is in good agreement with the value of $6.7 \pm 0.4 \times 10^{-3}$ deg $^{-2}$ reported in Ajello et al. (2009a).

In order to compare our results with the LogN–LogS measurements published elsewhere we adopt the following two strategies to convert fluxes from one band to another. In the first case we adopt a simple power law with a photon index of 2.0 which is known to describe generally well the spectra of faint AGN in the BAT band (Ajello et al. 2008b). Additionally we use a more complex model for the AGN emission in the BAT band which is based on the PEXRAV model of Magdziarz & Zdziarski (1995). In Burlon et al. (2011) the stacking of ~ 200 AGN spectra revealed that the average AGN spectrum is curved in the 15–200 keV band. This stacked AGN spectrum can be described using a PEXRAV model with a power-law index of 1.8, an energy cut-off of 300 keV and a reflection component due to a medium that covers an angle of 2π at the nuclear source ($R \approx 1$ in the PEXRAV model). These

parameters are reported in Tab. 1 of Burlon et al. (2011). To convert fluxes from the 15–55 keV band to the e.g. 14–195 keV band used by Tueller et al. (2008) the two factors are 2.02 and 1.92 (for the power law and PEXRAV model respectively). So we consider the uncertainty related to the flux conversion to be of the $\sim 5\%$ order.

We compare in Tab. 3 our results to those of Tueller et al. (2008), Cusumano et al. (2009) and Krivonos et al. (2010). When comparing INTEGRAL and BAT results one has to take into account the different normalizations of the Crab spectrum that the two instruments adopt (Krivonos et al. 2010). To make a proper comparison we convert the INTEGRAL 17–60 keV LogN–LogS to the 15–55 keV BAT band taking into account the different normalizations². It is apparent that there is excellent agreement with the results of Tueller et al. (2008) both in term of normalization of the LogN–LogS and also in term of its slope. Both slopes reported by Cusumano et al. (2009) and Krivonos et al. (2010) are in agreement with ours, but the density of AGN reported by Cusumano et al. (2009) is smaller than ours. We find an overall agreement within $\sim 10\%$ of our results and the ones of Krivonos et al. (2010) as Fig. 4 testifies.

We also compare the BAT results and the results of the population synthesis models of Gilli et al. (2007), Treister et al. (2009) and Draper & Ballantyne (2010). For both the Treister et al., and Draper & Ballantyne models we used the predictions for the 10–30 keV band reported in Ballantyne et al. (2011) while for the Gilli et al. (2007) model we use the 10–40 keV predictions available online³. Since BAT detects very few Compton-thick AGN we limited the predictions of the models of Gilli et al. (2007) and Draper & Ballantyne (2010) to objects with $\text{LogN}_H \leq 24$. The predictions by Treister et al. (2009) include objects with $\text{LogN}_H \geq 24$, however in their modeling the density of Compton-thick AGN is (at BAT sensitivities) $\sim 7\%$ of the total AGN population. The predictions of all models, converted to the BAT band using the above prescriptions, are compared to the BAT LogN–LogS in Fig. 3. It is apparent that there is good agreement with the BAT results at bright fluxes (i.e. $> 10^{-11} \text{ erg cm}^{-2} \text{ s}^{-1}$). At the limiting flux of our analysis (i.e. $\sim 6 \times 10^{-12} \text{ erg cm}^{-2} \text{ s}^{-1}$) the model predictions are beyond the statistical uncertainty of the BAT LogN–LogS as shown in Tab. 4 and in the inset of Fig. 3.

The model of Gilli et al. (2007) is compatible at bright fluxes with the BAT data, but

²In order to convert the INTEGRAL data to the BAT band we took into account that 1 BAT-mCrab in the 17–60 keV band is $1.22 \times 10^{-11} \text{ erg cm}^{-2} \text{ s}^{-1}$ while 1 INTEGRAL-mCrab is $1.43 \times 10^{-11} \text{ erg cm}^{-2} \text{ s}^{-1}$. Subsequently we converted the 17–60 keV fluxes to the 15–55 keV adopting a power law with an index of 2.0. This leads to $F_{15-55}^{BAT} = 0.878 F_{17-60}^{INTEGRAL}$.

³The Gilli et al. (2007) model is available at <http://www.bo.astro.it/~gilli/counts.html>.

with a steeper slope. On the other hand there seems to be a constant offset between the BAT LogN-LogS and the model predictions of Treister et al. (2009) and Draper & Ballantyne (2010). The model of Treister et al. (2009) reproduces the 14–195 keV BAT LogN-LogS of Tueller et al. (2008) which is in very good agreement with the one published here. However, a close inspection (see Fig. 1 in Treister et al. 2009) shows that the Tueller et al. (2008) data (reported in Treister et al. 2009) have a normalization ~ 1.6 larger than the original measurement reported in Tueller et al. (2008). Thus the Treister et al. (2009) is anchored to LogN-LogS data with a normalization ~ 1.6 larger than observed. This same factor is apparent when comparing the Treister et al. (2009) prediction to our data (see Tab. 4).

The model of Draper & Ballantyne (2010) reproduces (see their Fig. 3) the ‘correct’ 14–195 keV LogN-LogS as reported by Tueller et al. (2008). However, their 10–30 keV model prediction is at fluxes $\geq 10^{-14}$ erg cm $^{-2}$ s $^{-1}$ very similar to the one of Treister et al. (2009) and their predicted densities are a factor 1.6–1.8 larger than the measured ones in the 15–55 keV band (see Tab. 4) at the faintest fluxes sampled by our analysis. These findings might have some implications for the number of objects predicted to be detected by NuSTAR in serendipitous surveys above 10 keV (see § 5). Given the substantial agreement of the BAT and INTEGRAL LogN-LogS (see Fig. 4), it does not seem likely that the discrepancy in the predictions of synthesis models and the >10 keV LogN-LogS can be ascribed to a difference in the results above 10 keV.

3.2. The Luminosity Function

X-ray selected (below 10 keV) AGN are known to display a luminosity function that evolves with redshift (see e.g. Ueda et al. 2003; La Franca et al. 2005; Hasinger et al. 2005; Silverman et al. 2008; Aird et al. 2010). Our sample reaches a redshift of $z \approx 0.3$ where according to the above works, the evolution of AGN is significant and can potentially be detected. In Ajello et al. (2009b) we found marginal evidence for the evolution of AGN in the local Universe. Here we can make use of our all-sky sample of Seyfert galaxies to test this hypothesis. We adopt as a description of the X-ray luminosity function (XLF) a pure luminosity evolution model as follows:

$$\frac{dN}{dV dL_X} = \Phi(L_X(z), z) = \Phi(L_X/e(z)) \quad (3)$$

where V is comoving volume element and the evolution is parametrized using the common power-law evolutionary factor:

$$e(z) = (1 + z)^k \quad (4)$$

^aDensity at a 15–55 keV flux of $6 \times 10^{-12} \text{ erg cm}^{-2} \text{ s}^{-1}$.

^bTo convert the original 10–40 keV counts to the BAT 15–55 keV band we have used the following factors: 0.94 and 1.04 for the power law and PEXRAV model.

^cTo convert the 10–30 keV counts (reported in Ballantyne et al. 2011) to the BAT 15–55 keV band we have used the following factors: 1.18 and 1.40 for the power law and PEXRAV model.

Fig. 3.— LogN-LogS of the BAT AGN (black data points) and best power-law fit in the 15–55 keV band. The shaded gray region represents the 1σ uncertainty computed via bootstrap. The dashed lines show the predictions of the number counts from the models of Gilli et al. (2007), Treister et al. (2009), and Draper & Ballantyne (2010). The inset shows a close-up view of the distribution at the lowest fluxes.

We neglect any cut-off in the evolution as this takes place at a redshift that BAT cannot constrain (i.e. $z \approx 1$ see e.g. Aird et al. 2010). For the XLF at redshift zero we use a double power-law of the form:

$$\Phi(L_X, z = 0) = \frac{dN}{dL_X} = \frac{A}{\ln(10)L_X} \left[\left(\frac{L_X}{L_*} \right)^{\gamma_1} + \left(\frac{L_X}{L_*} \right)^{\gamma_2} \right]^{-1} \quad (5)$$

A value of k significantly different than zero would point towards an evolution of the XLF. In order to derive the luminosity function of AGN, we adopt the same maximum

Fig. 4.— LogN-LogS of the BAT AGN in the 15–55 keV band (filled circles) compared to the one derived from INTEGRAL data by Krivonos et al. (2010) (squares)

likelihood method described in Ajello et al. (2009b). In particular we determine the best-fit parameters of the XLF by finding the minimum of Eq. 11 in Ajello et al. (2009b).

In order not to include sources which could have a non negligible contribution to their total luminosity from X-ray binaries (see e.g. Voss & Ajello 2010) and to limit the incompleteness due to the bias against the detection of the most absorbed sources we derive the XLF only for $\text{Log}L_X \geq 41.3$. The best-fit parameters for the PLE model in case of evolution ($k \neq 0$) and in case of no evolution ($k = 0$) are reported in Tab. 5. The first result is that the model with no evolution (i.e. Eq. 5) represents a good description of the BAT dataset. The best-fit parameters are compatible with those reported by Sazonov et al. (2008), Tueller et al. (2008) and Ajello et al. (2009b).

Adding the extra k parameter produces only a marginal improvement in the fit. Indeed the log-likelihood improves only by ~ 5 which corresponds to a $\sim 2\sigma$ improvement (Wilks 1938). This is reflected in the luminosity evolution parameter which is constrained to be

$k=1.38\pm0.61$. The value found here is compatible, but smaller than the value of 2.62 ± 1.18 reported in Ajello et al. (2009b) showing that if there is evolution in the XLF of local AGN that might be shallower than previously found. We thus believe that the non-evolving XLF model is, in view of the marginal improvement of the goodness of fit, a better representation of the current dataset. Nevertheless, we will use the PLE model in § 5 to assess the level of uncertainty in the prediction for the number of AGN that might be detected by NuSTAR in a very near future.

It is interesting to compare our XLF with that one reported by Sazonov et al. (2008) and Tueller et al. (2008) in the 17–60 keV and in the 14–195 keV band respectively. Sazonov et al. (2008) and Tueller et al. (2008) report a value of the faint-end slope γ_1 of $0.76^{+0.18}_{-0.20}$ and $0.84^{+0.16}_{-0.22}$ respectively. The value of our faint-end slope is 0.78 ± 0.08 in agreement with both results, but much better constrained because of the larger dataset. When converted to our band (see previous section for the conversion factors), the break luminosity of Sazonov et al. (2008) and Tueller et al. (2008) is respectively $2.2^{+2.0}_{-1.0} \times 10^{43} \text{ erg s}^{-1}$ and $3.7^{+3.0}_{-1.6} \times 10^{43} \text{ erg s}^{-1}$ while we measure $5.1\pm1.4 \times 10^{43} \text{ erg s}^{-1}$ again compatible, but better constrained.

In order to display the LF we rely on the “ N^{obs}/N^{mdl} ” method devised by La Franca & Cristiani (1997) and Miyaji et al. (2001) and employed in several recent works (e.g. La Franca et al. 2005; Hasinger et al. 2005). Once a best-fit function for the LF has been found, it is possible to determine the value of the observed LF in a given bin of luminosity and redshift:

$$\Phi(L_{X,i}, z_i) = \Phi^{mdl}(L_{X,i}, z_i) \frac{N_i^{obs}}{N_i^{mdl}} \quad (6)$$

where $L_{X,i}$ and z_i are the luminosity and redshift of the i^{th} bin, $\Phi^{mdl}(L_{X,i}, z_i)$ is the best-fit LF model and N_i^{obs} and N_i^{mdl} are the observed and the predicted number of AGN in that bin.

Fig. 5 shows the best-fit non-evolving model (i.e. $k=0$) in comparison with the XLF of Sazonov et al. (2008) and Tueller et al. (2008). In general there is very good agreement between the XLFs derived in all these works. Our results are also in agreement with those obtained in the $<10 \text{ keV}$ band. Indeed, for the bright end slope Barger et al. (2005), La Franca et al. (2005) and Aird et al. (2010) obtain 2.2 ± 0.5 , $2.36^{+0.13}_{-0.11}$ and 2.55 ± 0.12 respectively while we measure 2.39 ± 0.12 . For the faint-end slope Barger et al. (2005), La Franca et al. (2005) and Aird et al. (2010) report 0.42 ± 0.06 , $0.97^{+0.08}_{-0.07}$ and 0.58 ± 0.04 ⁴ while we measure $\gamma_1=0.78\pm0.08$. The agreement for the faint-end slope is not as good as for the bright-end slope and there is some scatter (that appears to be systematic in origin) in the $<10 \text{ keV}$

⁴Aird et al. (2010) reports also 0.70 ± 0.03 for their PLE model.

measurement while there is substantial agreement above 10 keV (see above discussion). An excessive flatness of the faint-end slope might be linked to the role of Compton-thick AGN which are difficult to detect because the absorption pushes their observed luminosity below the survey threshold. Indeed, as shown in Burlon et al. (2011) 2–10 keV surveys are more biased in the detection of Compton-thick AGN than surveys above 10 keV. Depending on the redshift distribution of the sources (and thus on the k-correction) the bias might not be the same for different 2–10 keV surveys.

For completeness we also report in Tab. 5 the best-fit parameters to the XLF of all AGN excluding the Compton-thick ones of Tab.2. Because Compton-thick objects represent a small fraction of the AGN detected by BAT, there is very little difference between the XLF of all AGN and that of AGN with $\text{Log}N_H < 24$. However, in the next section this XLF will be useful to compare the space density of Compton-thick AGN to that of Compton-thin ($\text{Log}N_H < 24$) AGN.

3.3. The Space Density of Compton-thick AGN

We derive the space density of Compton-thick AGN with $24 \leq \text{Log}N_H \leq 25$ using the $1/V_{\text{MAX}}$ non-parametric method (Schmidt 1968). We de-absorb the luminosities of the BAT Compton-thick sources reported in Tab. 2 using the correction function reported in Burlon et al. (2011) (see their Fig. 11). This correction function was derived for the average properties of the Compton-thick AGN detected by BAT and takes into account photoelectric absorption as well as Compton scattering (see Murphy & Yaqoob 2009, for details).

Fig. 6 shows the luminosity function of the Compton-thick AGN detected by BAT while Fig. 7 reports the cumulative space density. In this latter case the uncertainty were computed via bootstrap with replacement. We find that the space density of Compton-thick AGN with a de-absorbed luminosity greater than $2 \times 10^{42} \text{ erg s}^{-1}$ is $7.9_{-2.9}^{+4.1} \times 10^{-5} \text{ Mpc}^{-3}$. Above a de-absorbed luminosity of $10^{43} \text{ erg s}^{-1}$ the density becomes $2.1_{-1.4}^{+1.6} \times 10^{-5} \text{ Mpc}^{-3}$. As shown in Fig. 6 the model predictions of Gilli et al. (2007) are compatible within the statistical error with our space density estimates. Treister et al. (2009) and Draper & Ballantyne (2010) estimated a space density of $\text{Log}L_X \geq 43 \text{ erg s}^{-1}$ sources of respectively $2.2_{-1.1}^{+2.9} \times 10^{-6} \text{ Mpc}^{-3}$ and $3\text{--}7 \times 10^{-6} \text{ Mpc}^{-3}$. These estimate are below ours, but compatible within 2σ and 1σ respectively.

In the same Fig. 6 we plot also the space density of AGN with $\text{Log}N_H < 24$ (from the previous section). While there is substantial agreement between the two, our analysis seems to point to the fact that the space density of Compton-thick AGN is larger than the one of

Fig. 5.— Luminosity function in the 15–55 keV band of the BAT AGN (non evolving model) compared with the measurements of Tueller et al. (2008) and Sazonov et al. (2008). The data point at a luminosity $< 2 \times 10^{41} \text{ erg s}^{-1}$ was not fitted to avoid problems related to incompleteness in detecting Compton-thick AGN and to avoid contamination from sources whose flux might be dominated by the emission of X-ray binaries (Voss & Ajello 2010).

all other classes of AGN. By allowing the normalization A of the XLF of $\text{Log}N_{\text{H}} < 24$ AGN to vary we find that $A_{\text{Log}N_{\text{H}} \geq 24} = 1.4 \times A_{\text{Log}N_{\text{H}} < 24}$: i.e. the space density of Compton-thick AGN is 1.4 times larger than that of $\text{Log}N_{\text{H}} < 24$ AGN. A similar results was obtained by Della Ceca et al. (2008b) who derived indirectly the space density of Compton-thick AGN as a difference between the density of optically selected AGN and that of X-ray selected AGN with $\text{Log}N_{\text{H}} < 24$ (see the aforementioned paper for more details). In their study they also find that the space density of Compton-thick AGN with $\text{Log}L_X \geq 43 \text{ erg s}^{-1}$ is $\sim 1.6 \times 10^{-5} \text{ Mpc}^{-3}$ which is in good agreement with the value found here.

Fig. 6.— Space densities of Compton-thick AGN detected by BAT compared to model prediction from Gilli et al. (2007) and the space density of Compton-thin ($\text{Log}N_{\text{H}} < 24$) AGN from § 3.2. Luminosities were de-absorbed following the method outlined in Burlon et al. (2011).

4. The Anisotropic Local Universe

The BAT sample represents an incredible resource to study the properties of the nearby Universe as it is a truly local sample of AGN. Indeed, the median redshift of the radio-quiet AGN detected by BAT is ~ 0.03 which corresponds to ~ 120 Mpc. On these scales the structure of the local Universe is known to be inhomogeneous and AGN are known to trace the matter density distribution (Cappelluti et al. 2010). The BAT AGN can thus be used to trace the large-local scale structure. Krivonos et al. (2007) reported, using 68 AGN detected by INTEGRAL, an anisotropy of the spatial distribution of local AGN. With an AGN sample ~ 6 times larger than the INTEGRAL sample it is possible to identify the anisotropic spatial distribution of AGN to a higher precision than previously obtained.

Fig. 7.— Cumulative space densities of Compton-thick AGN detected by BAT (thick red solid line) with 1σ confidence contours (dashed line) generated from the analysis of the bootstrapped samples (thin gray lines).

The following approach is adopted in order to assess the anisotropy of the spatial distribution of AGN. We first separate the sample in two redshift bins $z < 0.02$ and $0.02 \leq z \leq 0.15$ corresponding to a distance smaller (or greater) than 85 Mpc. The choice is dictated by the fact that the largest contrast in AGN density is expected to be observed nearby from us.

For each of these sub-samples we create a LogN–LogS that yields the average surface density of AGN for that redshift slice. Taking into account how the BAT sensitivity varies across the sky we generate (for each redshift bin) 1000 realizations of AGN sets which are isotropically distributed in the sky. Then for each direction in the sky we count how many AGN BAT has detected within a radius of 20° (typically this number oscillates around 10) versus the expected number for the isotropic case. For each of these sky positions we compute the fractional over-density of AGN: i.e. the ratio between the number of detected AGN and the number of expected objects if AGN were isotropically distributed. From the

1000 realizations we also compute the error (and the significance) connected to the fractional over-density.

Fig. 8 and Fig. 9 show how the fractional over-density of AGN (i.e. the ratio of detected AGN to the expected number for the isotropic case) and its significance change across the sky for the lower redshift bin. It is apparent that there is a marked contrast in the AGN density within 85 Mpc, with the AGN density varying by a factor of >10 across the sky. The most significant over-density is seen in the first redshift slice (i.e. within 85 Mpc) with prominent structures significant at $>4\sigma$.

There is a clear over-density of AGN (a factor >4 larger than the isotropic expectation) in the direction of the super-galactic plane. In particular the most dense region is found to be at $l = -54^\circ$ extending from $b \approx 15^\circ$ to $b \approx 50^\circ$. This corresponds to the position of the Hydra-Centaurus super-cluster ($z=0.01-0.02$) which represents one of the largest structures in the local Universe. The second most dense region (connecting to the south of the Hydra-Centaurus super-cluster) can likely be identified with the ‘Great Attractor’ (Lynden-Bell et al. 1988). In Fig. 8 the positions of the Great Attractor, the Centaurus and Hydra superclusters are shown with squares (from bottom left to upper right, respectively). The redshifts of the BAT AGN in these dense regions are in agreement with the redshifts of these massive structures. Our results appear to be in good agreement with the ones of Krivonos et al. (2007), but the improved statistics allow us to locate more precisely the over-density of AGN in the nearby Universe.

In the $0.02 \leq z \leq 0.15$ the anisotropy is less pronounced and less significant as well, with the most significant structures being $< 3\sigma$. A comparison with our simulations (which allow us to account for the trial factor) shows that the $0.02 \leq z \leq 0.15$ over-density map is indistinguishable (with the present data) from the isotropic expectation. However, the local environment is known to be highly inhomogeneous up to (at least) $z \approx 0.05$ (Jarrett 2004). The reason why BAT does not detect this anisotropy in the local scale structure is ultimately due to statistics. Indeed, the typical clustering length of the BAT AGN is known to be 5-8 Mpc (Cappelluti et al. 2010). Within 85 Mpc, our 20 degree search cone subtends⁵ a length of ~ 16 Mpc which is comparable to the clustering length of AGN. However, for the average redshift (~ 0.05) of the $0.02 \leq z \leq 0.15$ sample, the 20 degrees search cone subtends a length of 70 Mpc which is ten times larger than the typical clustering length of AGN. This contributes to dilute any over-density signal. In order to have a similar resolution as for the <85 Mpc sample, one should adopt a search cone of 5 degrees. However, with the current statistics we would expect less than 1 AGN in such cone.

⁵The average redshift of the $z < 0.02$ sample is 0.01.

Finally we checked if the anisotropy depends on any of the AGN parameters (i.e. flux, luminosity, type, etc.). To this extent we isolated the AGN in the direction of the Hydra-Centaurus super-clusters and of the Great Attractor and created a LogN–LogS and a luminosity function. The first result is that the XLF of these AGN is in good agreement with that of the entire population reported in Fig. 5. The LogN–LogS of the AGN in the direction of the super-clusters is shown, in comparison with the LogN–LogS of the whole population, in Fig. 10. It is clear that there is an excess at bright fluxes. This finding in conjunction with the fact that the XLF does not change indicates that the sources that contribute to the over-density are the brightest sources (i.e. the proximity of these local structures makes these sources appear with a bright flux). Indeed, the median redshift of the AGN in the direction of the super-clusters ($z \approx 0.015$) is markedly smaller than that of the whole population ($z \approx 0.03$).

It is also interesting to note that the fraction of Sy2 galaxies in the direction of the super-clusters is larger than average. Indeed, the fraction of objects classified as Sy2 in our whole sample and in the sample of Cusumano et al. (2010) is $\sim 34\%$ of the total AGN population. This ratio would increase to $\sim 45\%$ if all the objects with no optical classification reported in this or the Cusumano et al. (2010) sample would be in reality Sy2s. While it is reasonable to expect that more than 50% of the objects lacking an optical classification are Sy2 galaxies, it is unlikely that all of them are Sy2s. So this represents an extreme scenario.

The fraction of Sy2 object becomes $\sim 50\%$ if we consider only the AGN in the direction of the super-clusters and increases to $58 \pm 8\%$ if we restrict to sources within 85 Mpc. This seems in agreement with what reported by Petrosian (1982) that Sy1s are more often found to be isolated than Sy2s. In dense environments encounters between galaxies produce gravitational interactions that can trigger gas inflow towards the central hole and produce AGN activity. Galaxy merging is known to provide an efficient way to funnel large amount of gas and dust to the central black hole (e.g. Kauffmann & Haehnelt 2000; Wyithe & Loeb 2003; Croton et al. 2006). Recently, Koss et al. (2010) found that 24% of all the hosts of the BAT selected AGN have a companion galaxy within 30 kpc. This suggests that for a fraction of moderate luminosity AGN merging is a viable triggering mechanisms. However, in dense environments major merging is not the only process that might be at work. Indeed, galaxy harassments (i.e. high speed encounters between galaxies) can also drive most of the galaxy’s gas to the inner 500 pc (Lake et al. 1998) and thus trigger AGN activity. Also minor merging, where the ratio of the masses of the merging galaxies is >3 (and probably around ~ 10), can lead to Seyfert level of accretion (Hopkins & Hernquist 2009). With large quantities of gas available around the hole, in the early phase of accretion the AGN might have a higher probability of being identified as a type-2 AGN. This might explain the over-abundance of Sy2 galaxies in dense environments.

Fig. 8.— Fractional over-density of AGN with respect to the isotropic expectation within 85 Mpc. The color scale shows the ratio of BAT-detected AGN (within 20 degree cones) to the average number of AGN expected in the same area if sources were isotropically distributed. The map shows the regions where this ratio is the largest (red) and where it is the smallest (blue). The squares show the approximate position of the most prominent super-clusters (see text for details).

5. Predictions for NuSTAR

In this section we provide predictions for the number of objects that NuSTAR might see in different types of blank-field surveys. The predicted number counts are obtained by extrapolating the BAT LogN–LogS of § 3.1 to lower fluxes under the assumption that the slope of the LogN–LogS does not change. Indeed it is reasonable to expect so since there are strong indications both from observations in the 2–10 keV band and from modeling that the source count distribution breaks only at fluxes $\leq 10^{-14}$ erg cm $^{-2}$ s $^{-1}$.

The source count distribution of AGN is very well determined in the 2–10 keV band⁶ down to fluxes of $< 10^{-15}$ erg cm $^{-2}$ s $^{-1}$ (see e.g. Rosati et al. 2002; Cappelluti et al. 2007;

⁶For a typical AGN spectrum the 2–10 keV flux is on average 20 % larger than the 15–55 keV flux.

Fig. 9.— Significance of the density features of Fig. 8 expressed in number of σ .

Xue et al. 2011). Its slope is known to be Euclidean down to fluxes of $\sim 10^{-14} \text{ erg cm}^{-2} \text{ s}^{-1}$. For example Cappelluti et al. (2007) reports a slope of 2.43 ± 0.10 in good agreement with our results. A similar result is found by Rosati et al. (2002). Also population synthesis models predict a break in the LogN-LogS at $< 10^{-14} \text{ erg cm}^{-2} \text{ s}^{-1}$ (Gilli et al. 2007; Treister et al. 2009; Draper & Ballantyne 2010).

The extrapolation to fluxes a factor >50 fainter than those sample by BAT necessarily introduces some uncertainty related to neglecting the evolution of AGN. This uncertainty will be gauged later on in this section. However, the fact that BAT and NuSTAR sample (almost) the same energy band removes other sources of uncertainties. NuSTAR will likely perform three different types of surveys: a shallow, a medium and a deep survey. The shallow survey, performed combining short (5–10 ks) exposures, might extend over $\sim 3 \text{ deg}^2$ reaching fluxes⁷ $\sim 10^{-13} \text{ erg cm}^{-2} \text{ s}^{-1}$. The medium survey will likely cover $\sim 1 \text{ deg}^2$ with ~ 50 ks pointings reaching a 10–30 keV flux of $\sim 5 \times 10^{-14} \text{ erg cm}^{-2} \text{ s}^{-1}$ while the deep survey is

⁷Typical fluxes for NuSTAR are quoted for the 10–30 keV band. Here we have converted those fluxes to the 15–55 keV band adopting a power law with a photon index of 2.0.

Fig. 10.— LogN–LogS (15–55 keV) of the AGN in the direction of the Hydra-Centaurus super-clusters and of the Great Attractor compared to the LogN–LogS of all AGN.

expected to reach a 10–30 keV flux of $\sim 2 \times 10^{-14}$ erg cm⁻² s⁻¹ (using 200 ks pointings) over an area of ~ 0.3 deg².

Ballantyne et al. (2011) reported the number of expected AGN, in NuSTAR surveys, as predicted from different population synthesis models. Since the NuSTAR field of view is smaller than the surveyed area, NuSTAR will have to use a tiling strategy. Two tiling strategies can be foreseen: a corner shift and half-shift survey (see also Ballantyne et al. 2011). In the corner-shift strategy, the survey area is covered by non-overlapping pointing. In the half-shift strategy the distance between pointings is half the size of the FOV. The corner-shift strategy reaches deeper fluxes while the half-shift reaches a more uniform exposure of the surveyed area. Ballantyne et al. (2011) concluded that the half-shift strategy yields the larger number of AGN. Thus, in order to make a proper comparison we adopt the sky coverages reported by Ballantyne et al. (2011) for the half-shift tiling strategy for the 10–30 keV band. Converting the sky coverages from the 10–30 keV to the 15–55 keV is rather

easy and almost error free. Indeed for the power-law and the PEXRAV model discussed in § 3.1 we get a conversion factor of 1.16 and 1.18 respectively. Thus using a LogN-LogS derived in an overlapping band reduces the uncertainties due to flux conversion to less than $\sim 2\%$.

The number of objects predicted, extrapolating the LogN-LogS, for 4 different survey fields are reported in Tab. 6 and they are compared to the predictions of the models of Treister et al. (2009) and Draper & Ballantyne (2010) reported in Ballantyne et al. (2011). It is clear that our predictions lie substantially lower than the ones of population synthesis models. The left panel of Fig. 11 shows that (at NuSTAR sensitivities) the predictions of synthesis models lie a factor ~ 3 above the extrapolation of the LogN-LogS of BAT AGN.

This disagreement is likely due to two reasons. Part of it is due to the fact that synthesis models lie systematically above the BAT LogN-LogS as shown in § 3.1. The second one is that the simple extrapolation of the BAT LogN-LogS is not able to capture the evolution of AGN which is rather well established (e.g. Miyaji et al. 2001; La Franca et al. 2005; Hasinger et al. 2005) and expected also in the ≥ 10 keV band.

In order to correct for the first problem (i.e. the over-prediction of AGN in the BAT band) we arbitrarily renormalize the models of Gilli et al. (2007), Treister et al. (2009), and Draper & Ballantyne (2010) to fit the BAT data at bright fluxes and then we convolve them with the same sky coverages described above. The predictions for the ‘re-normalized’ models are reported in the lower part of Tab. 6 and are on average compatible within $\sim 1\sigma$ with the extrapolation of the BAT LogN-LogS (as also visible in the right panel of Fig. 11). This is reflected into a lower number of predicted AGN detections for NuSTAR in the 10–30 keV band.

In order to correct (or to gauge the uncertainty) due to neglecting any evolutionary effect in the LogN-LogS we rely on the best-fit PLE model of § 3.2. Even if marginally significant we take the best-fit parameters at their face value and derive the number of expected objects in NuSTAR fields. These are reported in the last row of Tab. 6. As it can be seen the prediction from the evolutionary XLF are in fairly good agreement with the predictions from the ‘normalized’ synthesis models. We thus believe this set of predictions (i.e. lower part of Tab. 6) for the number of AGN detectable is realistic. However, the ultimate number of detected AGN will likely depend on how the sensitivity will vary across the survey fields and, for the smallest fields, on cosmic variance.

Table 5. Parameters of fitted Luminosity Functions. Parameters without an error estimate were kept fixed during the fitting stage.

Model	A ^a	γ_1	γ_2	L_* ^b	k
No evolution	113.1±6.0 ^a	0.79±0.08	2.39±0.12	0.51±0.14	0
PLE	109.6±5.3 ^a	0.78±0.07	2.60±0.20	0.49±0.10	1.38±0.61
No evol., no CT	122.4±6.6 ^a	0.72±0.09	2.37±0.12	0.48±0.13	0

^aIn unit of 10^{-7} Mpc^{-3} .

^bIn unit of $10^{44} \text{ erg s}^{-1}$.

Table 6. Predictions for NuSTAR surveys adopting the half-shift coverages reported in Ballantyne et al. (2011). The lower part of the table shows the prediction of the models renormalized to match the BAT LogN–LogS.

Fig. 11.— LogN-LogS of the BAT AGN (black data points) and best power-law fit extrapolated to the sensitivity that NuSTAR will achieve. The left panel shows the original prediction of synthesis models, while in the right panel the predictions have been renormalized to match the AGN densities measured by BAT. In both panels the vertical dashed line shows the sensitivity reached by NuSTAR in a short pointing (i.e. 5–10 ks).

6. Summary and Conclusions

The analysis presented here shows the power of an all-sky survey at hard X-rays to study the AGN in our local environment. Thanks to the large field of view and high sensitivity BAT has detected 428 AGN all-sky above 10 keV with negligible ($\leq 5\%$) incompleteness. This represents the largest complete sample of AGN detected so far. Below we summarize our findings.

- The BAT AGN sample spans 10 decades in luminosity comprising objects detected at distance of ~ 1 Mpc up to redshift ~ 3.5 . The AGN sample can be divided into objects whose emission is dominated by the accretion disk/corona (i.e. Seyfert galaxies) and jet-dominated sources (i.e. blazars and radio galaxies). Seyfert galaxies are detected at low redshifts and low luminosities while jet-dominated sources, that are $\sim 15\%$ of the whole sample, are detected at high luminosity and high redshift.
- Samples of AGN detected above 10 keV are instrumental to determine the size of the population of Compton-thick AGN that are still detected in very little numbers. While a detailed measurement of the absorbing column density of all the AGN in the BAT sample is left to a future publication, we cross-correlated our sample with known

catalogs of bona-fide Compton-thick AGN. The BAT sample already comprises 15 (out of the 18 reported by Della Ceca et al. 2008a) bona-fide Compton-thick AGN and 3 likely candidates. The observed⁸ fraction of Compton-thick AGN, relative to the whole population, is thus $\sim 5\%$. We showed that BAT will likely not detect the rest of the known candidate Compton-thick AGN. Since the BAT sensitivity still improves with time, future AGN samples detected by BAT will likely contain previously unstudied Compton-thick AGN. A few (1 or 2 objects) might be present already in this sample.

- We performed a robust analysis, using bootstrapping, of the source counts distribution of the Seyfert-like objects detected by BAT. The BAT LogN–LogS is consistent with Euclidean down to the lowest fluxes spanned by this analysis (i.e. $6 \times 10^{-12} \text{ erg cm}^{-2} \text{ s}^{-1}$). The agreement between our and the INTEGRAL results (Krivonos et al. 2010) shows that the LogN–LogS of AGN selected above 10 keV is established to a precision of 10 %. The population synthesis models that we have tested (i.e. Gilli et al. 2007; Treister et al. 2009; Draper & Ballantyne 2010) are able to reproduce the BAT LogN–LogS at the brightest fluxes, but overestimate it at the lowest fluxes spanned by this analysis.
- We derived the luminosity function of (local) AGN and tested for its possible evolution with redshift. Even with our large sample of AGN the evidence for the evolution of the XLF are at best marginal (i.e. $\sim 2\sigma$). The BAT data are well described by a non-evolving XLF which is modeled as a standard double power law. We find that the slope of the faint end is $\gamma_1 = 0.79 \pm 0.08$ while that one of the bright end is $\gamma_2 = 2.39 \pm 0.12$. These values are in good agreement with those of Sazonov et al. (2008) and Tueller et al. (2008), but better constrained. Given the small FOV, NuSTAR will not be able to directly constrain the properties of the low-luminosities low-redshift AGN. The BAT sample and the BAT XLF are thus instrumental to determine, in connection with the future NuSTAR samples, the evolution and growth of AGN.
- We derived the luminosity function of Compton-thick AGN and found that at redshift zero their space density is $7.9^{+4.1}_{-2.9} \times 10^{-5} \text{ Mpc}^{-3}$ for objects with a de-absorbed luminosity larger than $2 \times 10^{42} \text{ erg s}^{-1}$. Our measurement is slightly larger, but compatible within uncertainties, with the prediction of synthesis models.
- The BAT samples of Seyfert galaxies is truly a local sample (median redshift 0.03) and can be used to study the spatial distribution of AGN in the local Universe. We

⁸See Burlon et al. (2011) for the bias that also instruments above 10 keV have in detecting Compton-thick AGN.

detected significant over-density features in the spatial distribution of AGN located within 85 Mpc. The densest regions show a density of AGN that is up to ~ 5 times larger than the average all-sky density. These dense regions can be identified with the most prominent nearby super-clusters: i.e. the Hydra-Centaurus super-cluster and the ‘Great Attractor’. The fraction of Sy2 galaxies (with respect to the total AGN population) appear to be larger than average in the direction of the over-dense regions. This evidence might support an evolutionary link where close encounters of galaxies trigger AGN activity whose first appearance is obscured by dust and gas.

- The BAT and the NuSTAR energy bands overlap and it is thus possible to derive straightforward predictions, from the LogN–LogS or the XLF, for the number of AGN that NuSTAR might detect in survey fields in the near future. We find substantial agreement in the number of predicted objects if the predictions of population synthesis models are renormalized to match, at the lowest fluxes, the BAT LogN–LogS.

Owing to the capability of detecting the local (those within ~ 200 Mpc), relatively low-luminosity AGN, but also high-redshift blazars, the all-sky hard X-ray surveys - such as the *Swift*-BAT survey discussed in this paper - have the unique potential to study simultaneously both the nearby and the early Universe. Such hard X-ray surveys represent a unique resource, since for many years, they will remain the most sensitive probes of the accretion history in the Universe.

MA acknowledges extensive discussions with Nico Cappelluti. MA acknowledges Ezequiel Treister and David Ballantyne for making the predictions from their models available in a machine readable format. The authors acknowledge the comments of the referee which helped improving this paper.
